ABSTRACT: Osteomyelitis is a dangerous and unforeseeable event in the treatment of bone fractures. In a 38-year-old patient, surgical treatment for leg fractures due to a domestic accident was complicated by osteomyelitis. To treat this severe complication, the following modality was followed: hardware removal, wide resection of the dead bone with debridement of the infected tissue, the implant of cement antibiotic-load spacer to fill the space, and a mono-axial external fixation. Subsequently, at the resolution of the infection, an Ilizarov external fixator was used, and a proximal tibia osteotomy was performed to obtain a distraction osteogenesis, while the gap at the distal tibia segment after the cement spacer removal was compressed. At the removal of the Ilizarov fixator, the clinical response was reasonable, but radiographically there was not a clear evidence of bone healing at the site of the previous fracture.

— Key words: Osteomyelitis, Infection, Leg fracture, External fixator, Ilizarov.

INTRODUCTION

Infections are one of the most important and fearsome complications following a fracture treatment. Surgical treatments, even if carefully performed, are still exposed to a high rate of infection. This unlucky event can involve different areas: hardware, bone, and soft tissues. The incidence of infection in orthopaedic trauma ranges from 5% to 10% depending on the location, the severity of the injury, the type of fracture, and the presence of microorganisms at the site of fracture1.

Osteomyelitis is one of the most dangerous complications, and its treatment is a challenge for the orthopaedic surgeon. There is still no scientific evidence to guide treatment of osteomyelitis1.

In the literature, many types of treatments are suggested in the management of infected non-unions of bones.

The Masquelet technique is widely used for the treatment of post-traumatic long-bone osteomyelitis2.

The “non-contact plate method”3 is another type of treatment proposed.

We report a case of osteomyelitis treated by the Ilizarov technique. The Ilizarov technique has been used in the UK for the last 20 years in the management of infected non-union of long bones. This method uses K-wires inserted percutaneously, which are implanted and tensioned to provide a strong frame construct4.

CASE PRESENTATION

A 38-year-old patient with no significant clinical history was admitted for a tibia fracture 43-C3 (A.O. classification) due to a domestic accident. Due to the involvement of soft-tissue, Tscherne type 2 fracture classification5 was initially treated in emergency with a skeletal-calcanueal traction. An open reduction internal fixation was performed after 10 days. The patient was administered general anaesthesia. We performed a lateral access to the distal part of the fibula. The fibula fracture was reduced with screws and a plate. Then, using a mini antero medial access to the distal region of the tibia, an open reduction and internal fixation with a plate and screws was performed together with two inter-fragmentary screws. During the post-operative controls two months after surgery, we noticed a surgical-swab dehiscence and an ulcer in the peri-malleolar region that had purulent secretion. The radiographic control showed fracture consolidation retar-
third time three months after the second surgery for a substitution of the external fixator. The mono-axial fixator was removed as the cement spacer. The bone margins were debrided, a proximal tibia and fibula osteotomy was performed, and an Ilizarov external fixator was used to compress the distal segment and to allow the osteogenetic distraction of the proximal segment. We proceeded with an elongation of 1 mm per day; after 30 days, 3 cm of bone elongation was reached. Five months after the last surgery, there were no radiographical or laboratory signs of infection neither, the limb length difference was corrected, the Ilizarov fixator was removed, and a short leg plaster cast was applied for three weeks. At the last follow-up at six months, the patient presented a reasonable clinical picture, but the radiographic control showed no clear sign of reparative callus at the fracture. At present, the patient is walking with a leg brace.

dation. The bloody PCR values during this period reached values of 218.7 mg/L (cut off 5 mg/l), and a wound swab gave results to positive *Staphylococcus aureus* beta-lactamase resistant infection. So, the patient was hospitalized again after three months. Rifampicin 600 mg BID was administered for seven days, then a moxifloxacin 400 mg/die therapy was started. A second surgery was performed using the incision of the previous surgical wound. We removed the hardware, resected 3 cm of the dead bone with wide debridement of the infected scarred soft tissue, implanted cement antibiotic-load spacer to fill the space, and a mono-axial external fixation was carried out to stabilize the bones. The intraoperative swab results were again positive to *Staphylococcus aureus* beta-lactamase resistant. The patient continued antibiotic therapy after the demission until the subsequent bloody control (PCR values, leucocytes) was found to be negative. The patient was hospitalized for a third time three months after the second surgery for a substitution of the external fixator. The mono-axial fixator was removed as the cement spacer. The bone margins were debrided, a proximal tibia and fibula osteotomy was performed, and an Ilizarov external fixator was used to compress the distal segment and to allow the osteogenetic distraction of the proximal segment. We proceeded with an elongation of 1 mm per day; after 30 days, 3 cm of bone elongation was reached. Five months after the last surgery, there were no radiographical or laboratory signs of infection neither, the limb length difference was corrected, the Ilizarov fixator was removed, and a short leg plaster cast was applied for three weeks. At the last follow-up at six months, the patient presented a reasonable clinical picture, but the radiographic control showed no clear sign of reparative callus at the fracture. At present, the patient is walking with a leg brace.

DISCUSSION

The Ilizarov technique combined with an appropriate antibiotic treatment is a good option for the surgical treatment of leg osteomyelitis.

In the literature, the results using the Ilizarov technique for the treatment of long-bone osteomyelitis, demonstrate a rate of success of more than 86%.6-8. The Ilizarov technique has been demonstrated to be comparable or better compared with other surgical techniques reported in the literature9,10.

The wide debridement of the bone and the soft tissue allow the removal of infection and non-vital tissue, reducing the risk of recurrent infections and the increase of post-operative complication such as delayed union, nonunion, and vascular thrombosis11. The use of an Ilizarov fixator allows the bone-gap recovery after the dead bone resection and the infected tissue debridement.

The possibility of early deambulation is another advantage of this type of treatment. The early deambulation represents a psychological benefit for the patient compared to other types of treatments. The mechanical stresses also represent a stimulation for bone remodeling12.

CONCLUSION

Ilizarov technique and antibiotic treatment represented a good strategy to manage Staphylococcal osteomyelitis, characterized by early deambulation without recurrent infections.
